

# Zero order methods

---

Now we have only zero order information from the oracle. Typical speed of convergence of these methods is sublinear. A lot of methods are referred both to zero order methods and global optimization.

## Travelling salesman problem

---

### Problem

---

Suppose, we have  $N$  points in  $\mathbb{R}^d$  Euclidian space (for simplicity we'll consider and plot case with  $d = 2$ ). Let's imagine, that these points are nothing else but houses in some 2d village. Salesman should find the shortest way to go through the all houses only once.

That is, very simple formulation, however, implies  $NP$ -hard problem with the factorial growth of possible combinations. The goal is to minimize the following cumulative distance:

$$d = \sum_{i=1}^{N-1} \|x_{y(i+1)} - x_{y(i)}\|_2 \rightarrow \min_y,$$

where  $x_k$  is the  $k$ -th point from  $N$  and  $y$  stands for the  $N$ -dimensional vector of indicies, which describes the order of path. Actually, the problem could be [formulated](#) as an LP problem, which is easier to solve.

## Genetic (evolution) algorithm

Our approach is based on the famous global optimization algorithm, known as evolution algorithm.

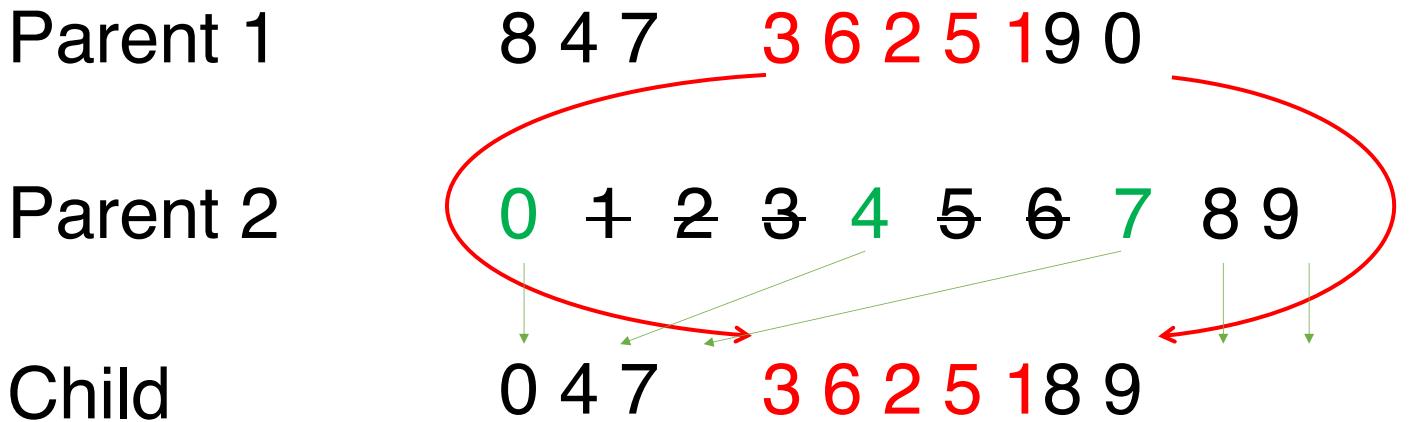

### Population and individuals

Firstly we need to generate the set of random solutions as an initialization. We will call a set of solutions  $\{y_k\}_{k=1}^n$  as *population*, while each solution is called *individual* (or creature).

Each creature contains integer numbers  $1, \dots, N$ , which indicates the order of bypassing all the houses. The creature, that reflects the shortest path length among the others will be used as an output of an algorithm at the current iteration (generation).

### Crossing procedure

Each iteration of the algorithm starts with the crossing (breed) procedure. Formally speaking, we should formulate the mapping, that takes two creature vectors as an input and returns its offspring, which inherits parents properties, while remaining consistent. We will use [ordered crossover](#) as such procedure.

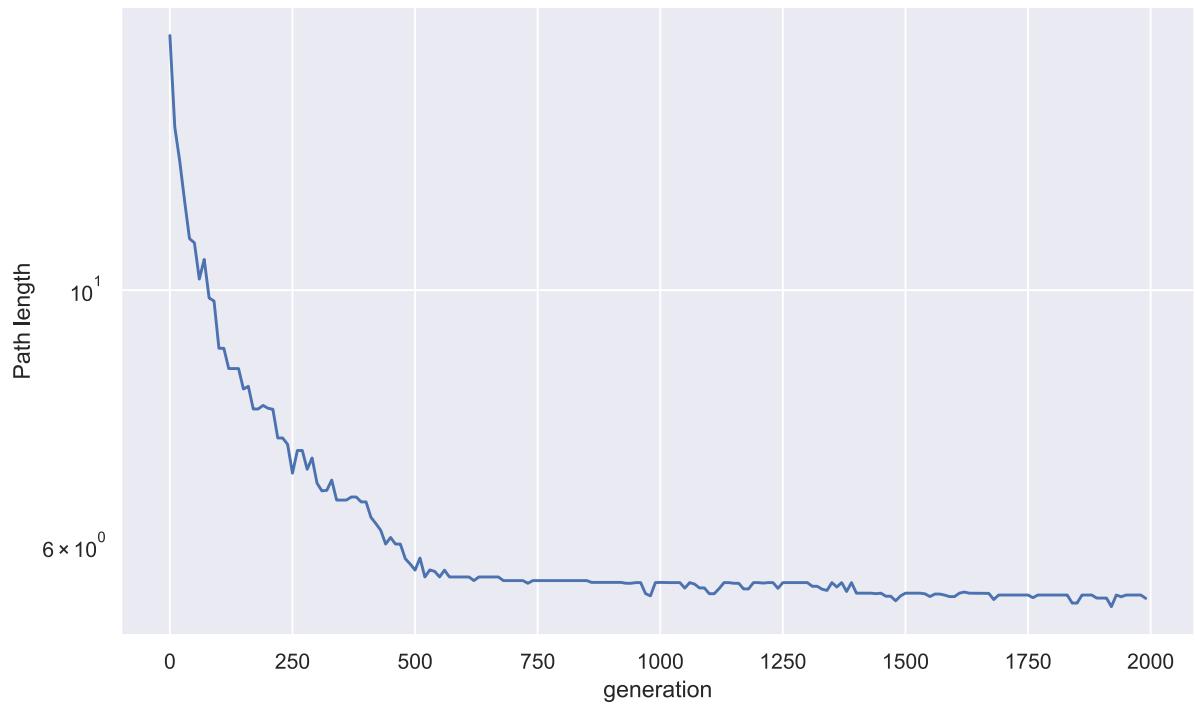

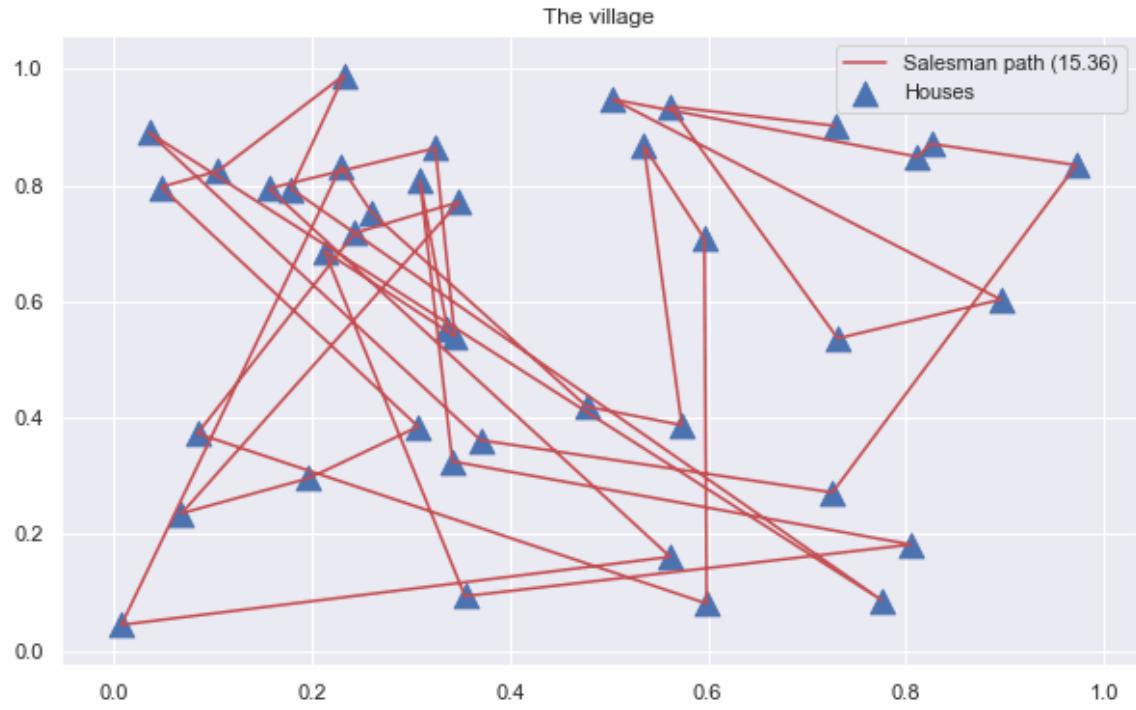

## Mutation

In order to give our algorithm some ability to escape local minima we provide it with mutation procedure. We simply swap some houses in an individual vector. To be more accurate, we define mutation rate (say, 0.05). On the one hand, the higher the rate, the less stable the population is, on the other, the smaller the rate, the more often algorithm gets stuck in the local minima. We choose **Error: '\_' allowed only in math mode** individuals and in each case swap random **Error: '\_' allowed only in math mode** digits.

## Selection

At the end of the iteration we have increased populatuion (due to crossing results), than we just calculate total path distance to each individual and select top  $n$  of them.

In general, for any  $c > 0$ , where  $d$  is the number of dimensions in the Euclidean space, there is a polynomial-time algorithm that finds a tour of length at most  $(1 + \frac{1}{c})$  times the optimal for geometric instances of TSP in

$$\mathcal{O}\left(N(\log N)^{(\mathcal{O}(c\sqrt{d}))^{d-1}}\right)$$

# Simulated annealing

---

## Problem

---

We need to optimize the global optimum of a given function on some space using only the values of the function in some points on the space.

$$\min_{x \in X} F(x) = F(x^*)$$

Simulated Annealing is a probabilistic technique for approximating the global optimum of a given function.

## Algorithm

---

The name and inspiration come from annealing in metallurgy, a technique involving heating and controlled cooling of a material to increase the size of its crystals and reduce their defects. Both are attributes of the material that depend on its thermodynamic free energy. Heating and cooling the material affects both the temperature and the thermodynamic free energy. The simulation of annealing can be used to find an approximation of a global minimum for a function with many variables.

## Steps of the Algorithm

**Step 1** Let  $k = 0$  - current iteration,  $T = T_k$  - initial temperature.

**Step 2** Let  $x_k \in X$  - some random point from our space

**Step 3** Let decrease the temperature by following rule  $T_{k+1} = \alpha T_k$  where  $0 < \alpha < 1$  - some constant that often is closer to 1

**Step 4** Let  $x_{k+1} = g(x_k)$  - the next point which was obtained from previous one by some random rule. It is usually assumed that this rule works so that each subsequent approximation should not differ very much.

**Step 5** Calculate  $\Delta E = E(x_{k+1}) - E(x_k)$ , where  $E(x)$  - the function that determines the energy of the system at this point. It is supposed that energy has the minimum in desired value  $x^*$ .

**Step 6** If  $\Delta E < 0$  then the approximation found is better than it was. So accept  $x_{k+1}$  as new started point at the next step and go to the step **Step 3**

**Step 7** If  $\Delta E \geq 0$ , then we accept  $x_{k+1}$  with the probability of  $P(\Delta E) = \exp^{-\Delta E/T_k}$ . If we don't accept  $x_{k+1}$ , then we let  $k = k + 1$ . Go to the step **Step 3**

The algorithm can stop working according to various criteria, for example, achieving an optimal state or lowering the temperature below a predetermined level  $T_{min}$ .

## Convergence

As it mentioned in [Simulated annealing: a proof of convergence](#) the algorithm converges almost surely to a global maximum.

## Illustration

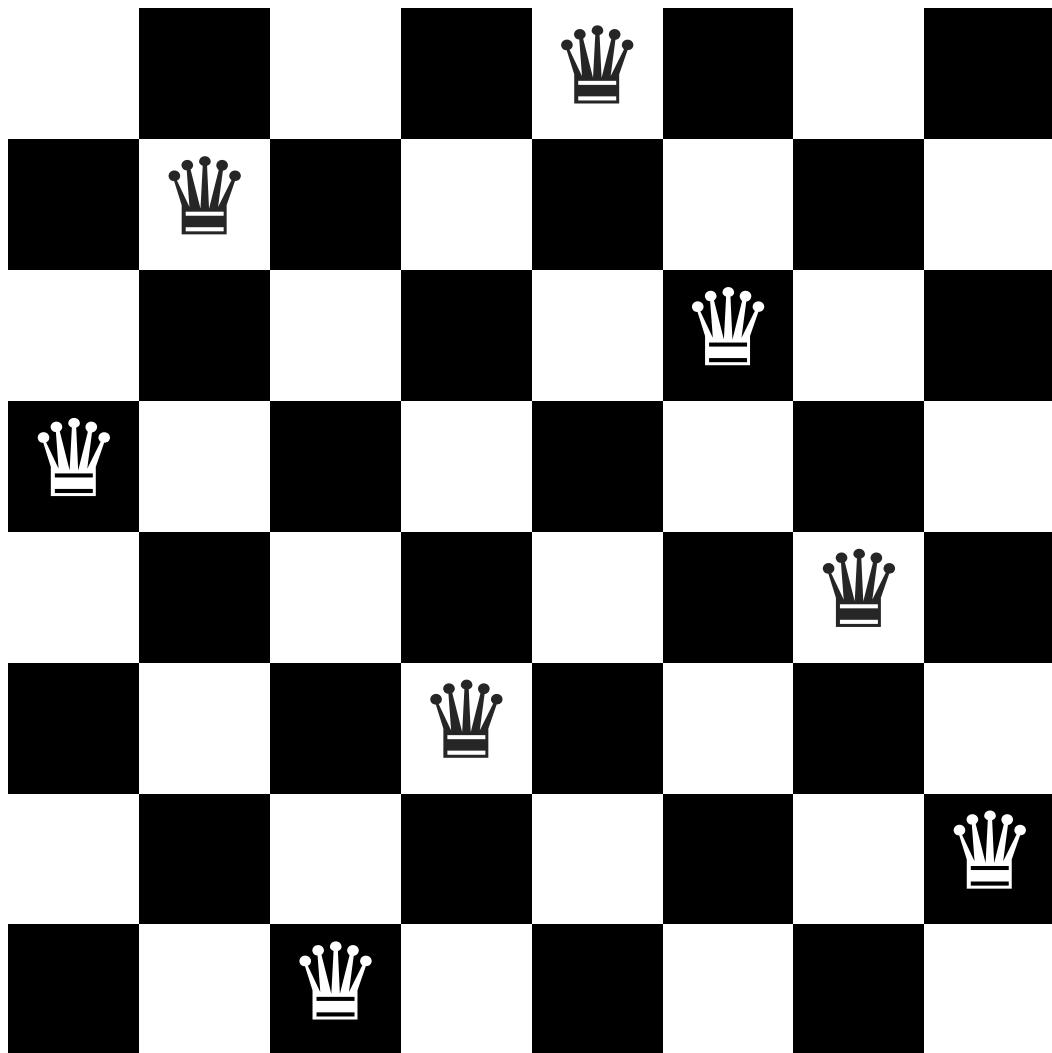

A gif from [Wikipedia](#):

## Example

---

In our example we solve the N queens puzzle - the problem of placing N chess queens on an  $N \times N$  chessboard so that no two queens threaten each other.

## The Problem

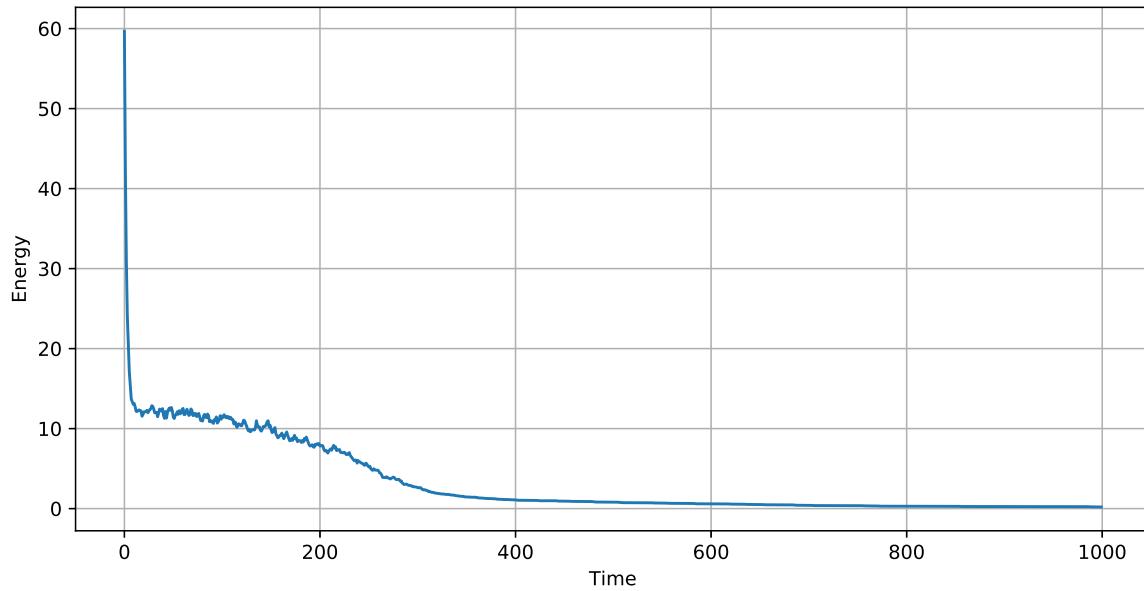

Let  $E(x)$  - the number of intersections, where  $x$  - the array of placement queens at the field (the number in array means the column, the index of the number means the row).

**The problem is** to find  $x^*$  where  $E(x^*) = \min_{x \in X} E(x)$  - the global minimum, that is predefined and equals to 0 (no two queens threaten each other).

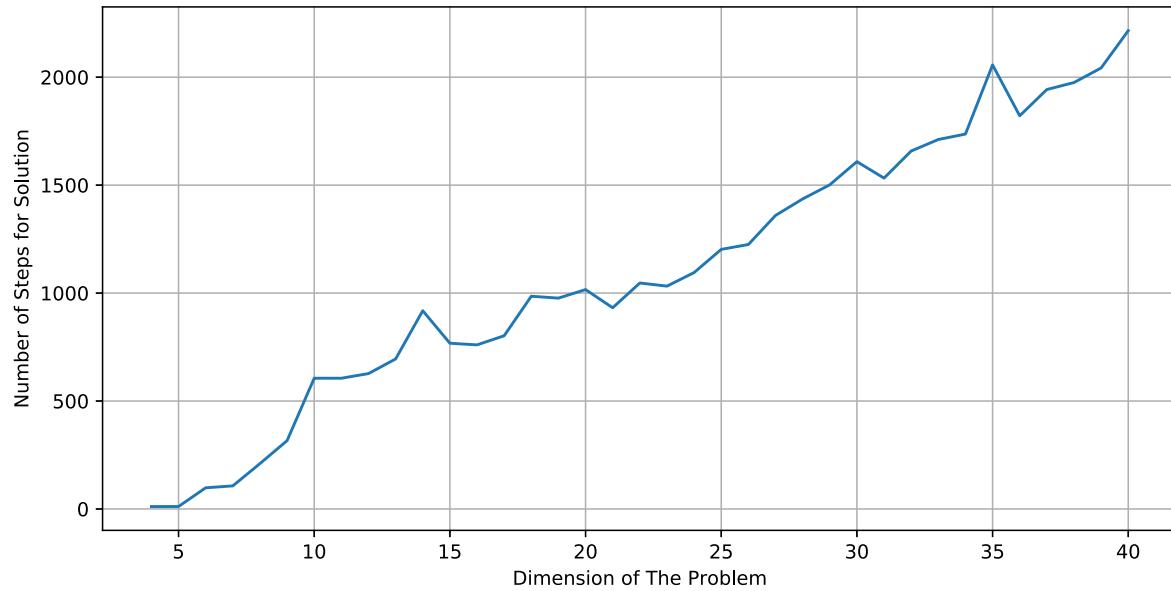

In this code  $x_0 = [0, 1, 2, \dots, N]$  that means all queens are placed at the board's diagonal . So at the beginning  $E = N(N - 1)$ , because every queen intersects others.

## Results

Results of applying this algorithm with  $\alpha = 0.95$  to the  $N$  queens puzzle for  $N = 10$  averaged by 100 runs are below:

Results of running the code for  $N$  from 4 to 40 and measuring the time it takes to find the solution averaged by 100 runs are below:

## Nelder-Mead

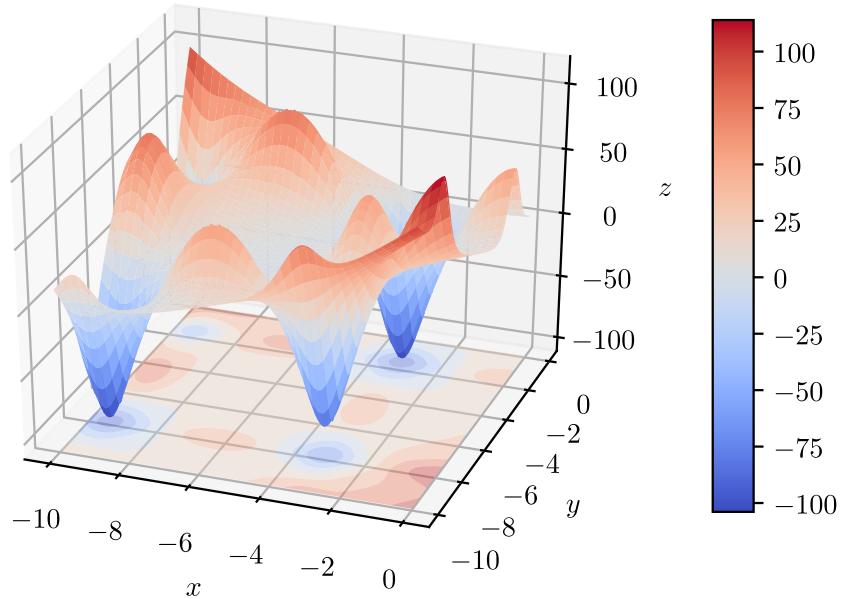

### Problem

Sometimes the multidimensional function is so difficult to evaluate that even expressing the 1<sup>st</sup> derivative for gradient-based methods of finding optimum becomes an impossible task.

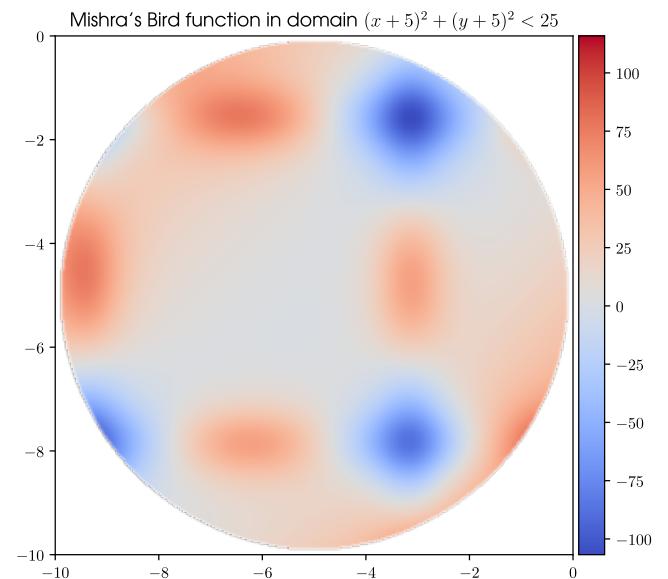

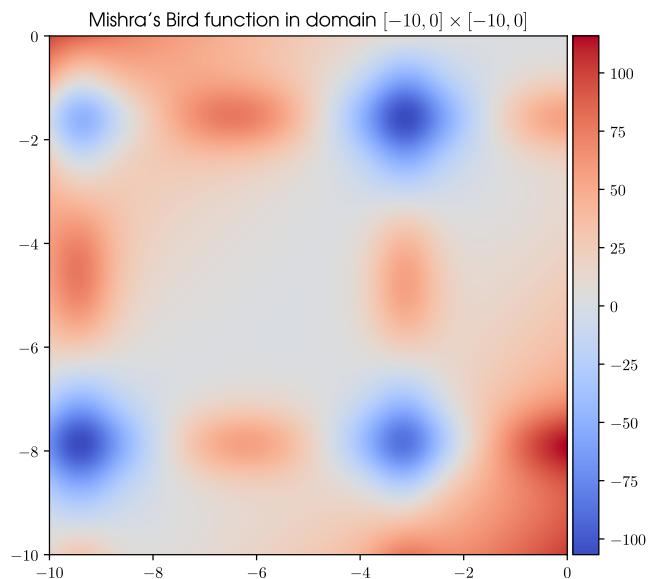

In this case, we can only rely on the values of the function at each point. Or, in other words, on the 0 order oracle calls.

Let's take, for instance, Mishra's Bird function:

$$f(x, y) = \sin y \cdot e^{(1-\cos x)^2} + \cos x \cdot e^{(1-\sin y)^2} + (x - y)^2$$

This function is usually subjected to the domain  $(x + 5)^2 + (y + 5)^2 < 25$ , but for the sake of picture beauty we will mainly use domain  $[-10; 0] \times [-10; 0]$ .

## Algorithm

---

## Related definitions:

- **Simplex** -- polytope with the least possible number of vertices in  $n$ -dimensional space. (So, it's  $(n + 1)$ -polytope.) In our  $2D$  case it will be triangle.
- **Best point**  $x_1$  -- vertex of the simplex, function value in which is the smallest among all vertices.
- **Worst point**  $x_{n+1}$  -- vertex of the simplex, function value in which is the largest among all vertices.
- **Other points**  $x_2, \dots, x_n$  -- vertices of the simplex, ordered in such way that  $f(x_1) \leq f(x_2) \leq \dots \leq f(x_n) \leq f(x_{n+1})$ .  
This implies that  $\{x_1, x_2, \dots, x_n\}$  are best points in relation to  $x_{n+1}$  and  $\{x_2, \dots, x_n, x_{n+1}\}$  are worst points in relation to  $x_1$ .
- **Centroid**  $x_o$  -- center of mass in the polytope. In Nelder-Mead the centroid is calculated for the polytope, constituted by best vertices.  
In our  $2D$  case it will be the center of the triangle side, which contains 2 best points  $x_o = \frac{x_1 + x_2}{2}$ .

## Main idea

The algorithm maintains the set of test points in the form of simplex. For each point the function value is calculated and points are ordered accordingly.

Depending on those values, the simplex exchanges the worst point of the set for the new one, which is closer to the local minimum. In some sense, the simplex is crawling to the minimal value in the domain.

The simplex movements finish when its sides become too small (termination condition by sides) or its area becomes too small (termination condition by area). I prefer the second condition, because it takes into account cases when simplex becomes degenerate (three or more vertices on one axis).

## Steps of the algorithm

### 1. Ordering

Order vertices according to values in them:

$$f(x_1) \leq f(x_2) \leq \dots \leq f(x_n) \leq f(x_{n+1})$$

Check the termination condition. Possible exit with solution  $x_{\min} = x_1$ .

### 2. Centroid calculation

$$x_o = \frac{\sum_{k=1}^n x_k}{n}$$

### 3. Reflection

Calculate the reflected point  $x_r$ :

$$x_r = x_o + \alpha (x_o - x_{n+1})$$

where  $\alpha$  -- reflection coefficient,  $\alpha > 0$ . (If  $\alpha \leq 0$ , reflected point  $x_r$  will not overlap the centroid)

The next step is figured out according to the value of  $f(x_r)$  in dependency to values in points  $x_1$  (best) and  $x_n$  (second worst):

- $f(x_r) < f(x_1)$ : Go to step 4.
- $f(x_1) \leq f(x_r) < f(x_n)$ : new simplex with  $x_{n+1} \rightarrow x_r$ . Go to step 1.
- $f(x_r) \geq f(x_n)$ : Go to step 5.

#### 4. Expansion

Calculate the expanded point  $x_e$ :

$$x_e = x_o + \gamma (x_r - x_o)$$

where  $\gamma$  -- expansion coefficient,  $\gamma > 1$ . (If  $\gamma < 1$ , expanded point  $x_e$  will be contracted towards centroid, if  $\gamma = 1$ :  $x_e = x_r$ )

The next step is figured out according to the ratio between  $f(x_e)$  and  $f(x_r)$ :

- $f(x_e) < f(x_r)$ : new simplex with  $x_{n+1} \rightarrow x_e$ . Go to step 1.
- $f(x_e) > f(x_r)$ : new simplex with  $x_{n+1} \rightarrow x_r$ . Go to step 1.

#### 5. Contraction

Calculate the contracted point  $x_c$ :

$$x_c = x_o + \beta (x_{n+1} - x_o)$$

where  $\beta$  -- contraction coefficient,  $0 < \beta \leq 0.5$ . (If  $\beta > 0.5$ , contraction is insufficient, if  $\beta \leq 0$ , contracted point  $x_c$  overlaps the centroid)

The next step is figured out according to the ratio between  $f(x_c)$  and  $f(x_{n+1})$ :

- $f(x_c) < f(x_{n+1})$ : new simplex with  $x_{n+1} \rightarrow x_c$ . Go to step 1.
- $f(x_c) \geq f(x_{n+1})$ : Go to step 6.

#### 6. Shrinkage

Replace all points of simplex  $x_i$  with new ones, except for the best point  $x_1$ :

$$x_i = x_1 + \sigma (x_i - x_1)$$

where  $\sigma$  -- shrinkage coefficient,  $0 < \sigma < 1$ . (If  $\sigma \geq 1$ , shrunked point  $x_i$  overlaps the best point  $x_1$ , if  $\sigma \leq 0$ , shrunked point  $x_i$  becomes extended)

Go to step 1.

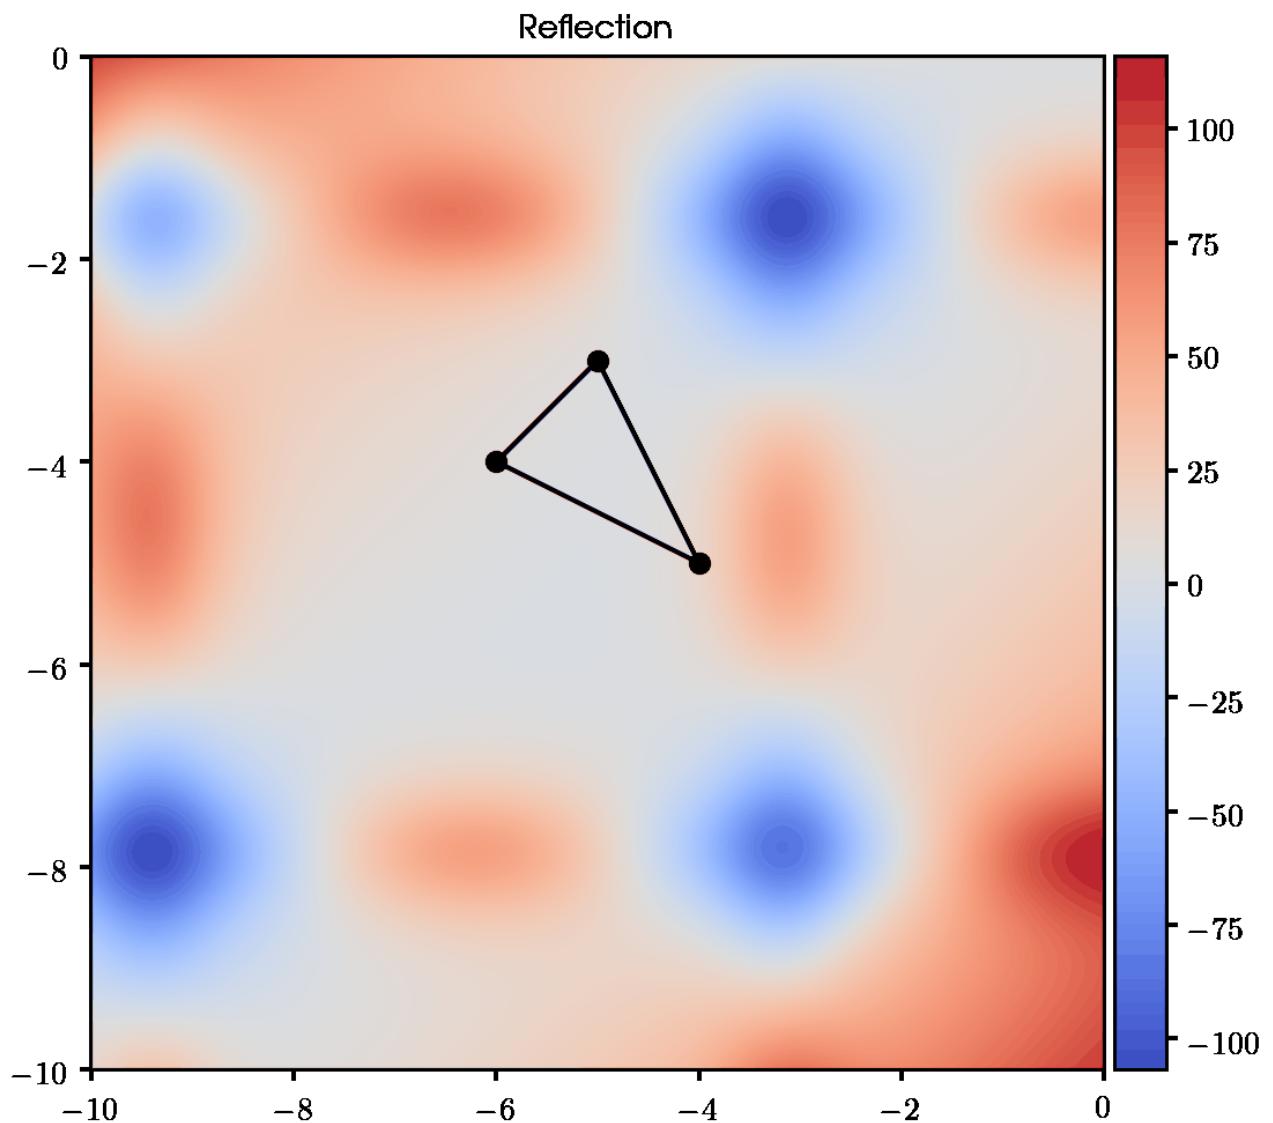

## Examples

---

This algorithm, as any method in global optimization, is highly dependable on the initial coonditions. For instance, if we use different initial simplex or different set of parameters  $\{\alpha, \beta, \gamma, \sigma\}$  the resulting optimal point will differ.

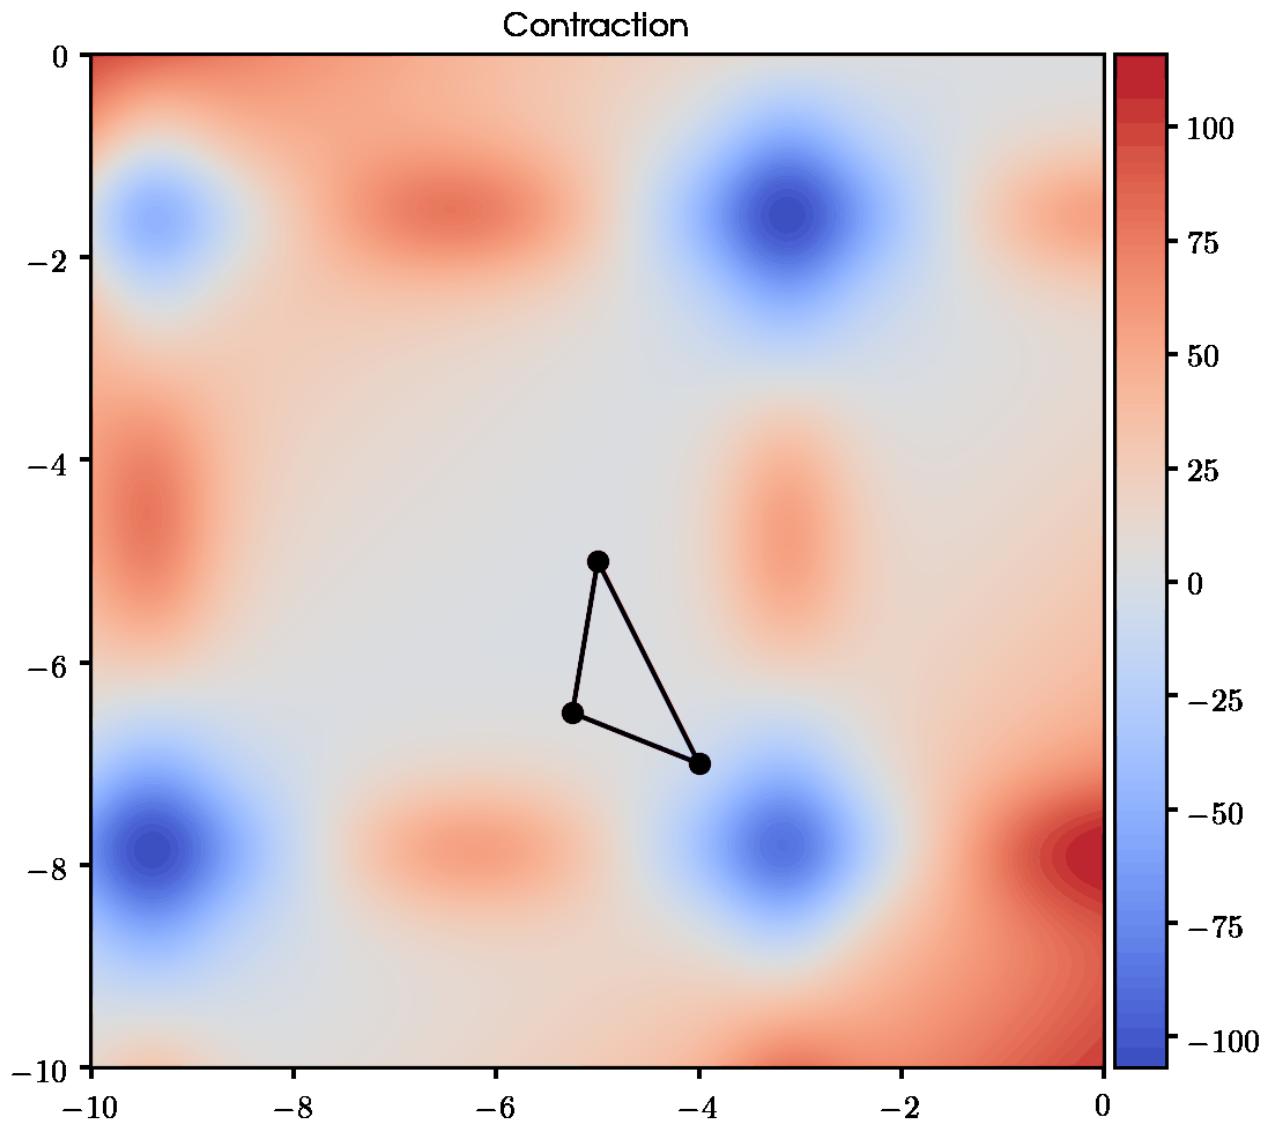

## Some random initial simplex and default set of parameters

Nelder-Mead on Mishra's Bird function in domain  $[-10, 0] \times [-10, 0]$   
 $\alpha = 1.0, \beta = 0.5, \gamma = 2.0, \sigma = 0.5$

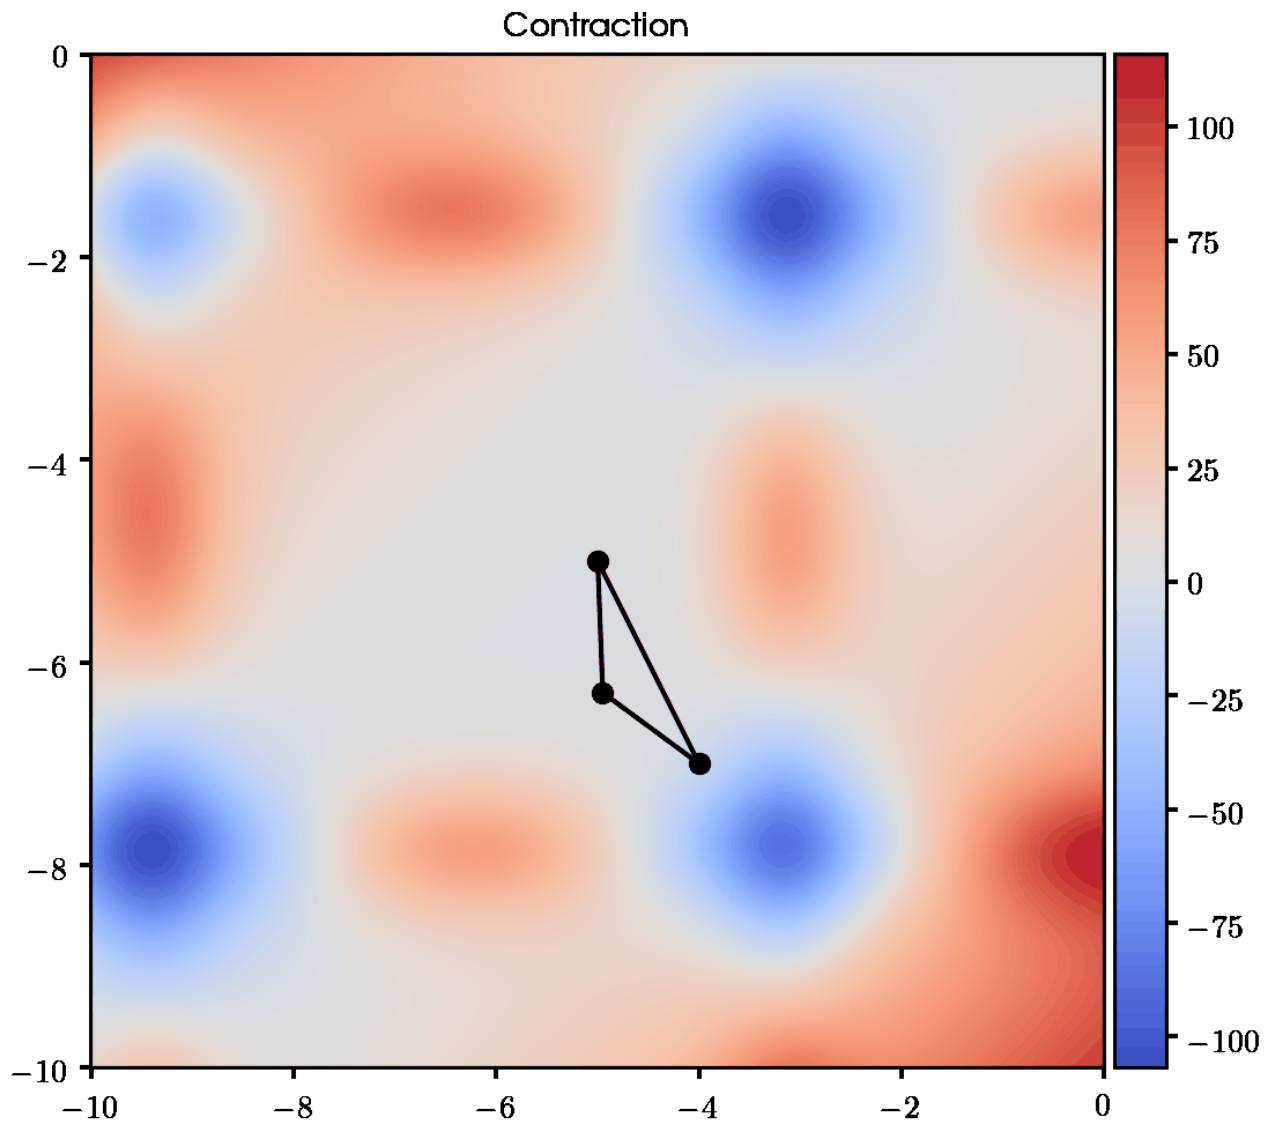

## Different initial simplex and same set of parameters

Nelder-Mead on Mishra's Bird function in domain  $[-10, 0] \times [-10, 0]$   
 $\alpha = 1.0, \beta = 0.5, \gamma = 2.0, \sigma = 0.5$

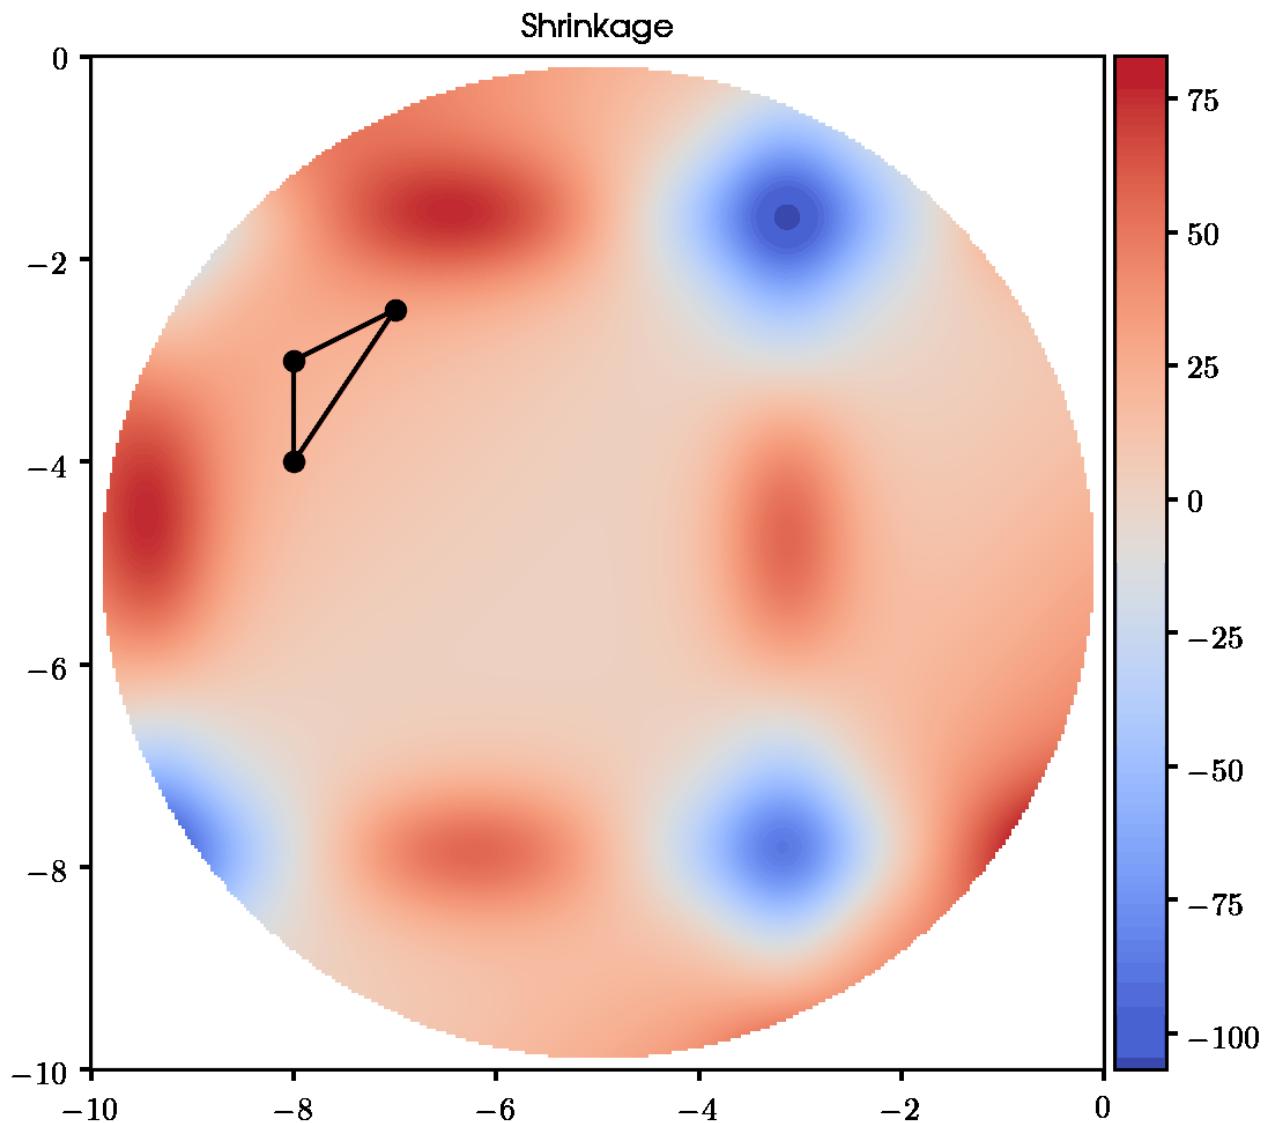

Same initial simplex and different set of parameters

Nelder-Mead on Mishra's Bird function in domain  $[-10, 0] \times [-10, 0]$   
 $\alpha = 3.0, \beta = 0.3, \gamma = 5.0, \sigma = 0.5$

Round domain

Nelder-Mead on Mishra's Bird function in domain  $(x + 5)^2 + (y + 5)^2 < 25$   
 $\alpha = 1.0, \beta = 0.5, \gamma = 2.0, \sigma = 0.5$

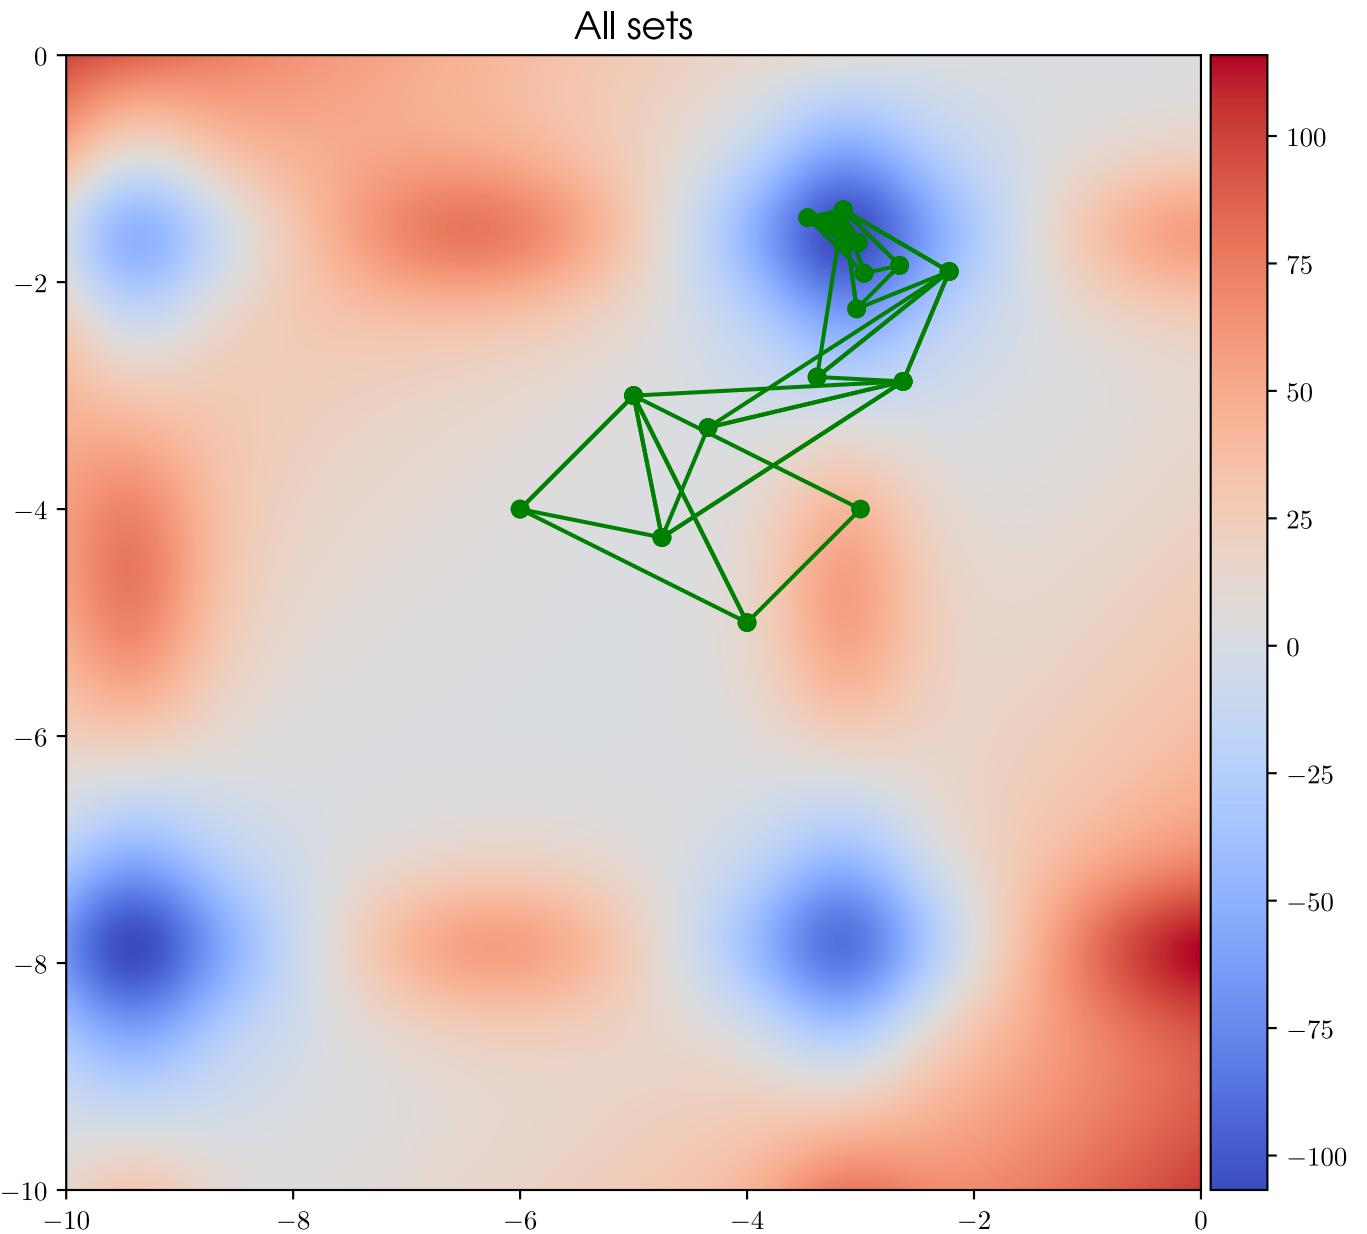

Examples with all sets of simplexes

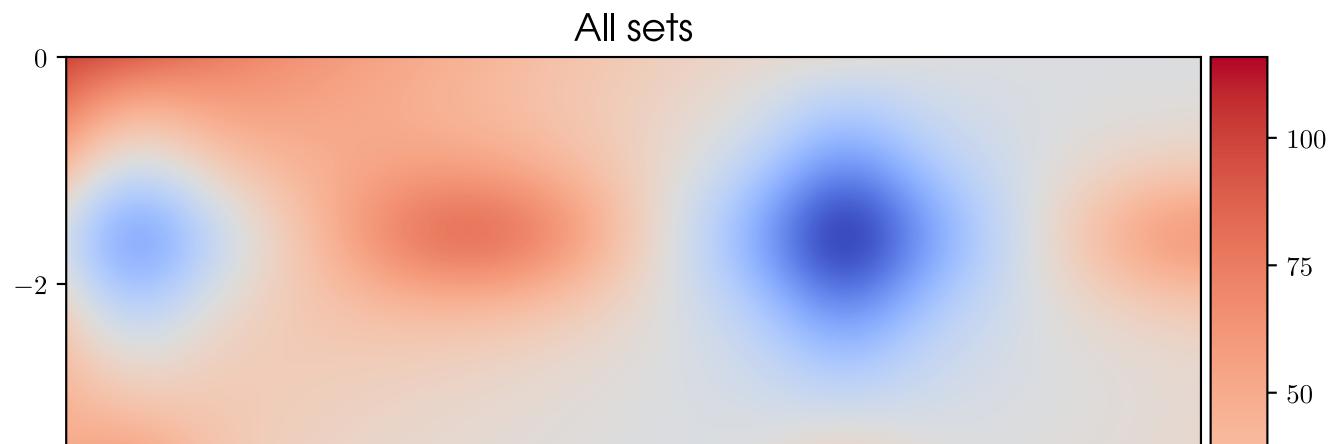

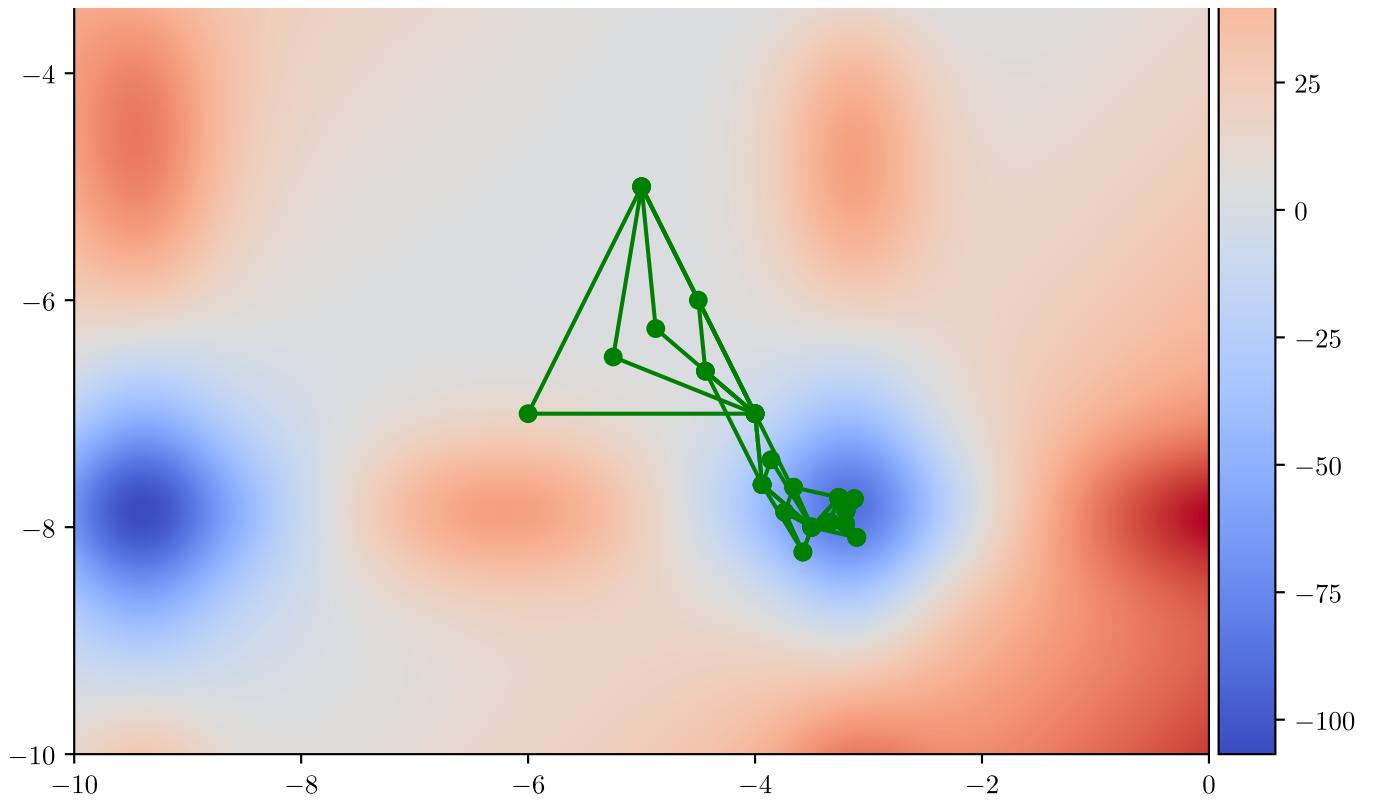

Nelder-Mead on Mishra's Bird function in domain  $[-10, 0] \times [-10, 0]$   
 $\alpha = 1.0, \beta = 0.5, \gamma = 2.0, \sigma = 0.5$

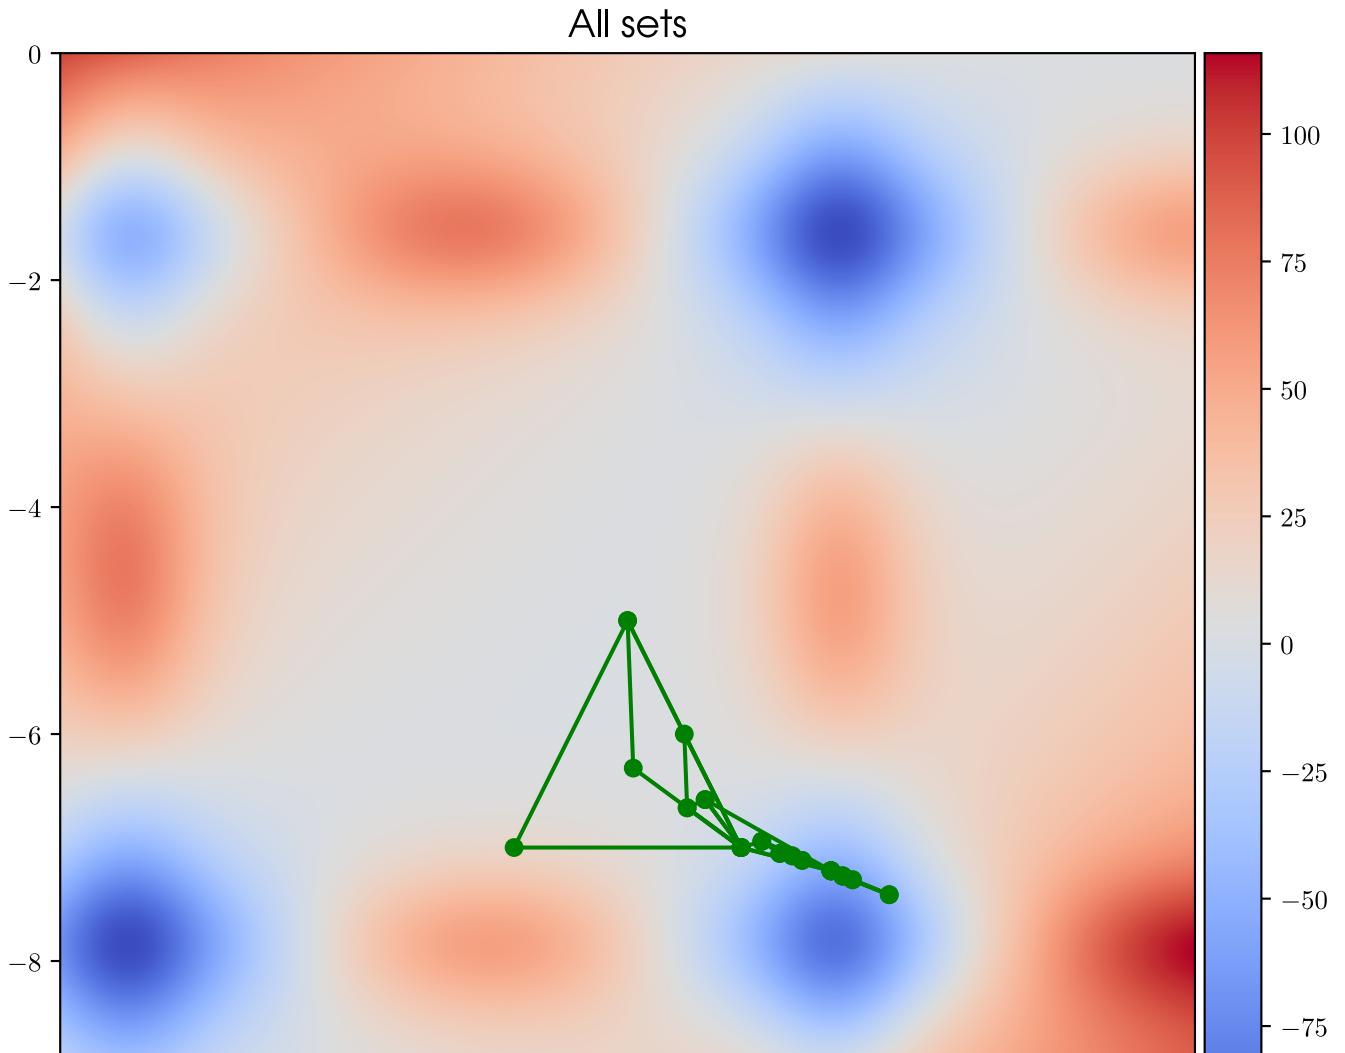

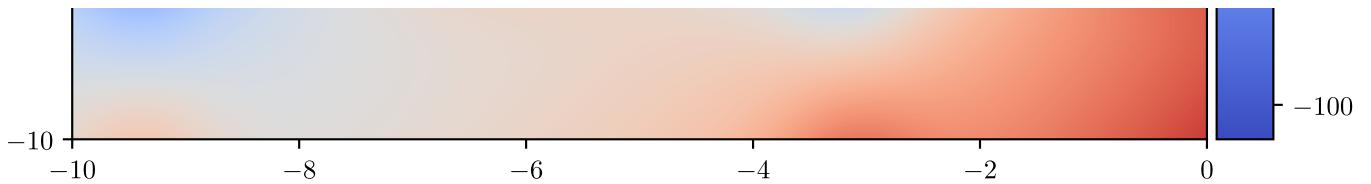

Nelder-Mead on Mishra's Bird function in domain  $[-10, 0] \times [-10, 0]$   
 $\alpha = 1.0, \beta = 0.5, \gamma = 2.0, \sigma = 0.5$

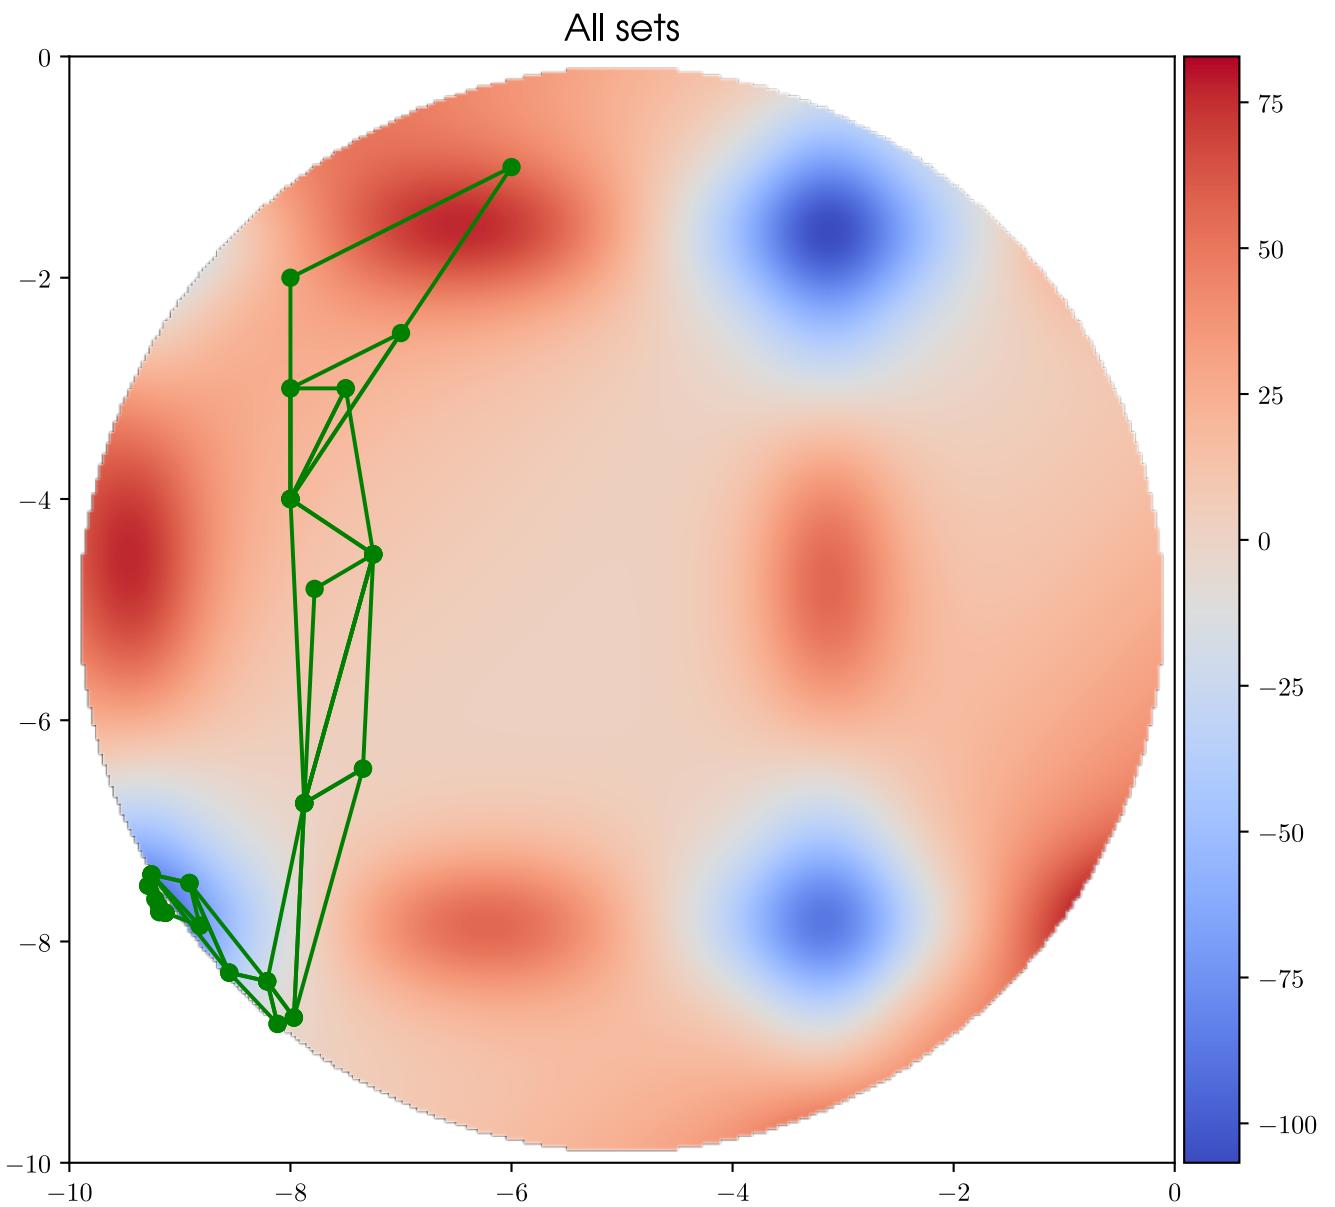

Nelder-Mead on Mishra's Bird function in domain  $[-10, 0] \times [-10, 0]$   
 $\alpha = 3.0, \beta = 0.3, \gamma = 5.0, \sigma = 0.5$

Nelder-Mead on Mishra's Bird function in domain  $(x + 5)^2 + (y + 5)^2 < 25$   
 $\alpha = 1.0, \beta = 0.5, \gamma = 2.0, \sigma = 0.5$

## Code

[Open in Colab](#)

### Example 1

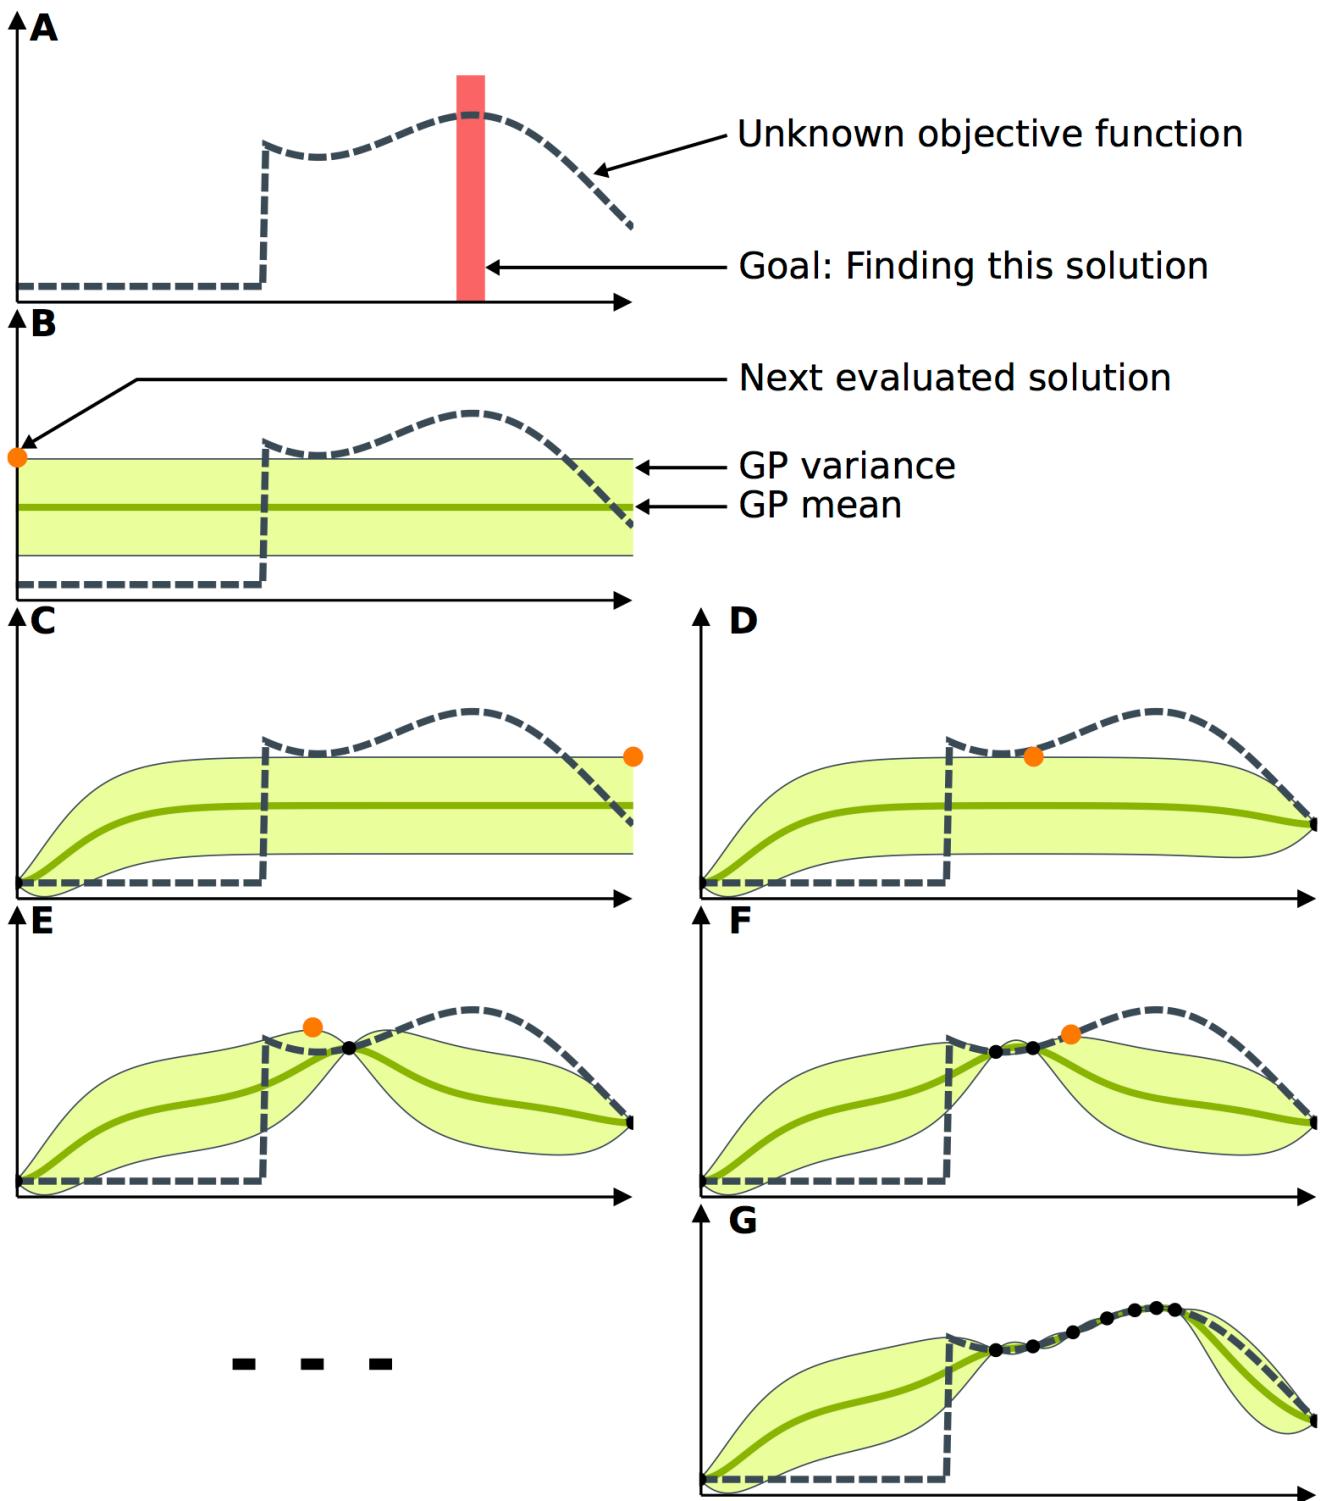

Implement Rastrigin function  $f : \mathbb{R}^d \rightarrow \mathbb{R}$  for  $d = 10$ . [link](#)

$$f(\mathbf{x}) = 10d + \sum_{i=1}^d [x_i^2 - 10 \cos(2\pi x_i)]$$

- Consider global optimization from [here](#).
- Try to plot 4 graphs for different  $d$  from {10, 100, 1000, 10000}. On each graph you are to plot  $f$  from  $N_{fev}$  for 5 methods: `basinhopping`, `brute`, `differential_evolution`, `shgo`, `dual_annealing` from `scipy`, where  $N_{fev}$  - the number of function evaluations. This information is usually available from `specific_optimizer.nfev`. If you will need bounds for the optimizer, use  $x_i \in [-5, 5]$ .

## Example 2

Machine learning models often have hyperparameters. To choose optimal one between them one can use GridSearch or RandomSearch. But these algorithms computationally uneffective and don't use any sort of information about type of optimized function. To overcome this problem one can use [bayesian optimization](#). Using this method we optimize our model by sequentially choosing points based on prior information about function.

In this task you will use [optuna](#) package for hyperparameter optimization RandomForestClassifier. Your task is to find best Random Forest model varying at least 3 hyperparameters on iris dataset. Examples can be find [here](#) or [here](#)

```
```bash
!pip install optuna
```

```

```
```python
import sklearn.datasets
import sklearn.ensemble
import sklearn.model_selection
import sklearn.svm

import optuna

iris = sklearn.datasets.load_iris()
x, y = iris.data, iris.target
```
```

### Example 3

Try to perform hyperparameter optimization in context of any metric for imbalanced classification problem with optuna and keras.  [Open in Colab](#)
